# PAGERANK ALGORITHM

# PageRank

- Consider the graph at the right
  - These could be webpages with links shown in the corresponding direction
  - These could be neighboring cities
- PageRank generally tries to answer the question:
  - **If we let a bunch of people randomly "walk" the graph, what is the probability that they end up at a certain location (page, city, etc.) in the "steady-state"**
- We could solve this problem through Monte-Carlo simulation (similar to CS 103 Coin-flipping game assignment)
  - Simulate a large number of random walkers and record where each one ends to build up an answer of the probabilities for each vertex
- But there are more efficient ways of doing it

# PageRank

- Let us write out the adjacency matrix for this graph
- Now let us make a weighted version by normalizing based on the out-degree of each node
  - Ex. If you're at node B we have a 50-50 chance of going to A or E
- From this you could write a system of linear equations (i.e. what are the chances you end up at vertex I at the next time step, given you are at some vertex J now)
  - $p_A = 0.5 * p_B$
  - $p_B = p_C$
  - $p_C = p_A + p_D + 0.5 * p_E$
  - $p_D = 0.5 * p_E$
  - $p_E = 0.5 * p_B$
  - We also know:  $p_A + p_B + p_C + p_D + p_E = 1$

# PageRank

- System of Linear Equations
  - $p_A = 0.5 \cdot p_B$
  - $p_B = p_C$
  - $p_C = p_A + p_D + 0.5 \cdot p_E$
  - $p_D = 0.5 \cdot p_E$
  - $p_E = 0.5 \cdot p_B$
  - We also know:  $p_A + p_B + p_C + p_D + p_E = 1$
- If you know something about linear algebra, you know we can write these equations in matrix form as a linear system
  - $Ax = y$

Source=j

# PageRank

- But remember we want the steady state solution
  - The solution where the probabilities don't change from one step to the next
- So we want a solution to:  $\mathbf{A}p = p$
- We can:
  - Use a linear system solver (Gaussian elimination)
  - Or we can just seed the problem with some probabilities and then just iterate until the solution settles down

$$\begin{vmatrix} 0 & 0.5 & 0 & 0 & 0 \\ 0 & 0 & 1 & 0 & 0 \\ 1 & 0 & 0 & 1 & 0.5 \\ 0 & 0 & 0 & 0 & 0.5 \\ 0 & 0.5 & 0 & 0 & 0 \end{vmatrix} * \begin{vmatrix} pA \\ pB \\ pC \\ pD \\ pE \end{vmatrix} = \begin{vmatrix} pA \\ pB \\ pC \\ pD \\ pE \end{vmatrix}$$

	.3077
	.0769
	.1538

# Additional Notes

- What if we change the graph and now D has no incoming links...what is its PageRank?
  - 0
- Most PR algorithms add a probability that someone just enters that URL (i.e. enters the graph at that node)
  - Usually define something called the damping factor,  $\alpha$  (often chosen around 0.85)
  - Probability of randomly starting or jumping somewhere =  $1-\alpha$
- So at each time step the next PR value for node  $i$  is given as:

$$\text{Pr}(i) = \frac{1-\alpha}{N} + \alpha * \sum_{j \in \text{Pred}(i)} \frac{\text{Pr}(j)}{\text{OutDeg}(j)}$$

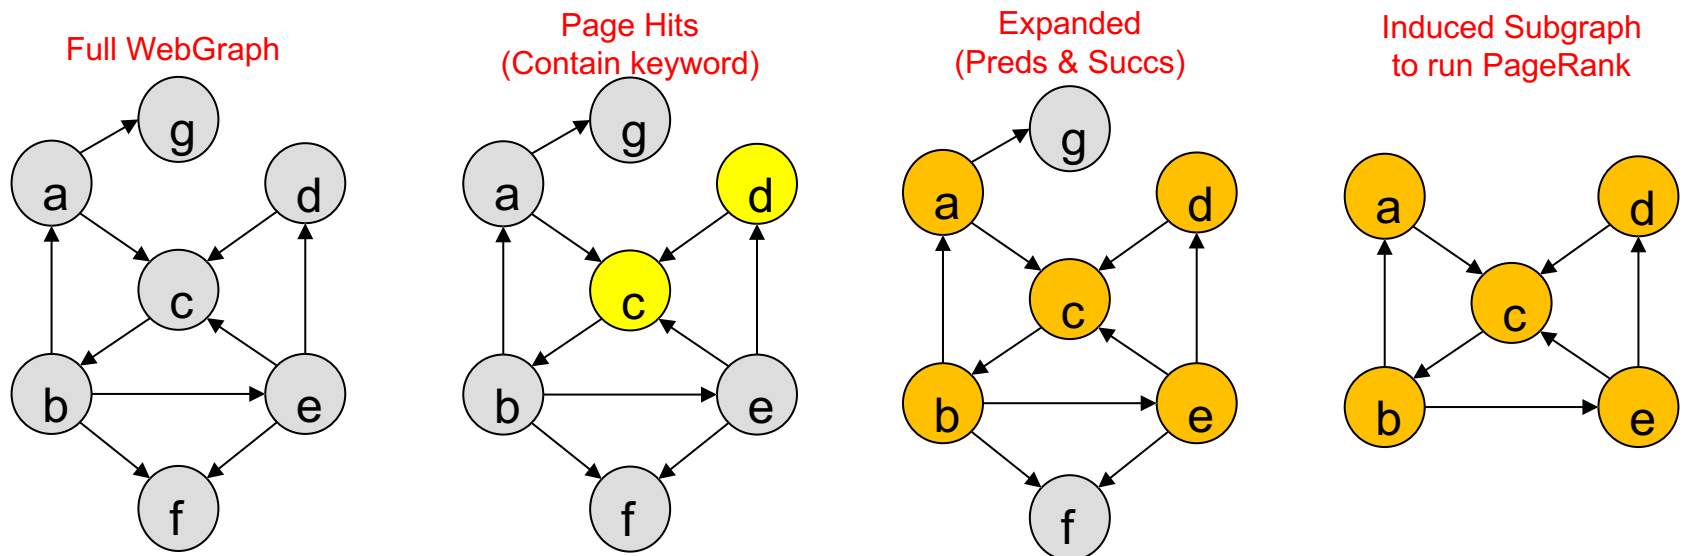

- $N$  is the total number of vertices
- Usually run 30 or so update steps
- Start each  $\text{Pr}(i) = 1/N$

# In a Web Search Setting

- Given some search keywords we could find the pages that have that matching keywords
- We often expand that set of pages by including all successors and predecessors of those pages
  - Include all pages that are within a radius of 1 of the pages that actually have the keyword
- Now consider that set of pages and the subgraph that it induces
- Run PageRank on that subgraph

Dijkstra's Algorithm

# **SINGLE-SOURCE SHORTEST PATH (SSSP)**

# SSSP

- Let us associate a 'weight' with each edge
  - Could be physical distance, cost of using the link, etc.
- Find the shortest path from a source node, 'a' to all other nodes

# Dijkstra's Algorithm

- Dijkstra's algorithm is similar to a BFS but pulls out the smallest distance vertex (from the source) rather than pulling vertices out in FIFO order (as in BFS)
- Maintain a data structure that you can identify shortly
  - We'll show it as a table of all vertices with their currently 'known' distance from the source
    - Initially, a has dist=0
    - All others = infinite distance

9	-

# Analysis

- What is the loop invariant? What can I say about the vertex I pull out from the PQ?
  - It is guaranteed that there is no shorter path to that vertex
  - UNLESS: negative edge weights
- Could use induction to prove
  - When I pull the first node out (it is the start node) it's weight has to be 0 and that is definitely the shortest path to itself
  - I then "relax" (i.e. decrease) the distance to neighbors it connects to and the next node I pull out would be the neighbor with the shortest distance from the start
    - Could there be shorter path to that node?
  - No, because any other path would use some other edge from the start which is already greater than the edge to this node

# Dijkstra's Run-time Analysis

- What is the run-time of Dijkstra's algorithm?
- How many times do you execute the while loop on 8?
  - V total times because once you pull a node out each iteration
  - That node is guaranteed to have found its shortest distance to the start
  - What does each call to `remove_min()` cost...
  - $\dots \log(V)$  [at most V items in PQ]
- How many total times do you execute the for loop on 10?
  - E total times: Visit each vertex's neighbors
  - Each iteration may call `decreaseKey()` which is  $\log(V)$
- Total runtime =  $V \cdot \log(V) + E \cdot \log(V) = (V+E) \cdot \log(V)$ 
  - This is usually dominated by  $E \cdot \log(V)$

```
1.  SSSP(G, s)
2.  PQ = empty PQ
3.  s.dist = 0; s.pred = NULL
4.  PQ.insert(s)
5.  For all v in vertices
6.    if v != s then v.dist = inf;
7.    PQ.insert(v)
8.  while PQ is not empty
9.    v = min(); PQ.remove_min()
10.   for u in neighbors(v)
11.     w = weight(v,u)
12.     if(v.dist + w < u.dist)
13.       u.pred = v
14.       u.dist = v.dist + w;
15.       PQ.decreaseKey(u, u.dist)
```

# Tangent on Heaps/PQs

- Suppose min-heaps
  - Though everything we're about to say is true for max heaps but for increasing values
- We know insert/remove is  $\log(n)$  for a heap
- What if we want to decrease a value already in the heap...
  - Example: Decrease 26 to 9
  - Could we find 26 easily?
    - No requires a linear search through the array/heap =>  $O(n)$
  - Once we find it could we adjust it easily?
    - Yes, just promote it until it is in the right location =>  $O(\log n)$
- So currently decrease-key() would cost  $O(n) + O(\log n) = O(n)$
- Can we do better?

# Tangent on Heaps/PQs

- Can we provide a `decrease-key()` that runs in  $O(\log n)$  and not  $O(n)$ 
  - Remember we'd have to first find then promote
- We need to know where items sit in the heap
  - Essentially we want to quickly know the location given the key (i.e. Map key  $\Rightarrow$  location)
  - Unfortunately storing the heap as an array does just the opposite (maps location  $\Rightarrow$  key)
- What if we maintained an alternative map that did provide the reverse indexing
  - Then I could find where the key sits and then promote it
- If I keep that map as a balanced BST can I achieve  $O(\log n)$ 
  - No! each promotion swap requires update your location and your parents
  - $O(\log n)$  swaps each requiring lookup(s) in the location map [ $O(\log n)$ ] yielding  $O(\log^2(n))$

	0	1	2	3	4	5	6	7	8	9	10	11	12	13

Map of key to loc.	0	1	2	3	4	5	6	7	8	9	10	11	12	13

# Tangent on Heaps/PQs

- Am I out of luck then?
- No, try a hash map
  - $O(1)$  lookup
- Now each swap/promotion up the heap only costs  $O(1)$  and thus I have:
  - Find  $\Rightarrow O(1)$ 
    - Using the hashmap
  - Promote  $\Rightarrow O(\log n)$ 
    - Bubble up at most  $\log(n)$  levels with each level incurring  $O(1)$  updates of locations in the hashmap
- Decrease-key() is an important operation in the next algorithm we'll look at

A\* Search Algorithm

# ALGORITHM HIGHLIGHT

# Search Methods

- Many systems require searching for goal states
  - Path Planning
    - Roomba Vacuum
    - Mapquest/Google Maps
    - Games!!
  - Optimization Problems
    - Find the optimal solution to a problem with many constraints

# Search Applied to 8-Tile Game

- 8-Tile Puzzle
  - 3x3 grid with one blank space
  - With a series of moves, get the tiles in sequential order
  - Goal state:

1	2	3
4	5	6
7	8	

Goal State for these  
slides

# Search Methods

- **Brute-Force Search:** When you don't know where the answer is, just search all possibilities until you find it.
- **Heuristic Search:** A heuristic is a “rule of thumb”. An example is in a chess game, to decide which move to make, count the values of the pieces left for your opponent. Use that value to “score” the possible moves you can make.
  - Heuristics are not perfect measures, they are quick computations to give an approximation (e.g. may not take into account “delayed gratification” or “setting up an opponent”)

# Brute Force Search

- Brute Force Search Tree

- Generate all possible moves
- Explore each move despite its proximity to the goal node

# Heuristics

- Heuristics are “scores” of how close a state is to the goal (usually, lower = better)
- These scores must be easy to compute (i.e. simpler than solving the problem)
- Heuristics can usually be developed by simplifying the constraints on a problem
- Heuristics for 8-tile puzzle
  - # of tiles out of place
    - Simplified problem: If we could just pick a tile up and put it in its correct place
  - Total x-, y- distance of each tile from its correct location (Manhattan distance)
    - Simplified problem if tiles could stack on top of each other / hop over each other

1	8	3
4	5	6
2	7	

**# of Tiles out of Place = 3**

1	8	3
4	5	6
2	7	

**Total x-/y- distance = 6**

# Heuristic Search

- Heuristic Search Tree
  - Use total x-/y-distance (Manhattan distance) heuristic
  - Explore the lowest scored states

# Caution About Heuristics

- Heuristics are just estimates and thus could be wrong
- Sometimes pursuing lowest heuristic score leads to a less-than optimal solution or even no solution
- Solution
  - Take # of moves from start (depth) into account

# A-star Algorithm

- Use a new metric to decide which state to explore/expand
- Define
  - $h$  = heuristic score (same as always)
  - $g$  = number of moves from start it took to get to current state
  - $f = g + h$
- As we explore states and their successors, assign each state its  $f$ -score and always explore the state with lowest  $f$ -score
- Heuristics should always underestimate the distance to the goal
  - If they do,  $A^*$  guarantees optimal solutions

# A-Star Algorithm

- Maintain 2 lists
  - Open list = Nodes to be explored (chosen from)
  - Closed list = Nodes already explored (already chosen)
- Pseudocode

**open\_list.push(Start State)**

**while(open\_list is not empty)**

- 1.  $s \leftarrow$  remove min. f-value state from open\_list**  
(if tie in f-values, select one w/ larger g-value)
- 2. Add s to closed list**
- 3a. if  $s$  = goal node then trace path back to start; STOP!**
- 3b. Generate successors/neighbors of s, compute their f values, and add them to open\_list if they are not in the closed\_list (so we don't re-explore), or if they are already in the open list, update them if they have a smaller f value**

# Path-Planning w/ A\* Algorithm

- Find optimal path from S to G using A\*
  - Use heuristic of Manhattan (x-/y-) distance

**\*\*If implementing this for a programming assignment, please see the slide at the end about alternate closed-list implementation**

```

open_list.push(Start State)
while(open_list is not empty)
  1. s ← remove min. f-value state from
    open_list (if tie in f-values, select one w/
    larger g-value)
  2. Add s to closed list
  3a. if s = goal node then
    trace path back to start; STOP!
  3b. else
    Generate successors/neighbors of s,
    compute their f-values, and add them to
    open_list if they are not in the closed_list
    (so we don't re-explore), or if they are
    already in the open list, update them if
    they have a smaller f value

Open List

# A\* and BFS

- BFS explores all nodes at a shorter distance from the start (i.e. g value)

# A\* and BFS

- BFS explores all nodes at a shorter distance from the start (i.e. g value)

# A\* and BFS

- BFS is A\* using just the g value to choose which item to select and expand

# A\* Analysis

- What data structure should we use for the open-list?
- What data structure should we use for the closed-list?
- What is the run time?
- Run time is similar to Dijkstra's algorithm...
  - We pull out each node/state once from the open-list so that incurs  $N \cdot O(\text{remove-cost})$
  - We then visit each successor which is like  $O(E)$  and perform an insert or decrease operation which is like  $E \cdot \max(O(\text{insert}), O(\text{decrease}))$
  - $E$  = Number of potential successors and this depends on the problem and the possible solution space
  - For the tile puzzle game, how many potential boards are there?

**open\_list.push(Start State)**

**while(open\_list is not empty)**

**1.  $s \leftarrow$  remove min. f-value state from open\_list**  
**(if tie in f-values, select one w/ larger g-value)**

**2. Add s to closed list**

**3a. if  $s$  = goal node then trace path back to start; STOP!**

**3b. Generate successors/neighbors of s, compute their f values, and add them to open\_list if they are not in the closed\_list (so we don't re-explore), or if they are already in the open list, update them if they have a smaller f value**

# Implementation Note

- When the distance to a node/state/successor (i.e., g value) is uniform, we can greedily add a state to the closed-list at the same time as we add it to the open-list

Non-uniform g-values

open\_list.push(Start State)

while(open\_list is not empty)

1.  $s \leftarrow$  remove min. f-value state from open\_list  
(if tie in f-values, select one w/ larger g-value)

2. Add  $s$  to closed list

3a. if  $s$  = goal node then trace path back to start; STOP!

3b. Generate successors/neighbors of  $s$ , compute their f values, and add them to open\_list if they are not in the closed\_list (so we don't re-explore), or if they are already in the open list, update them if they have a smaller f value

Uniform g-values

open\_list.push(Start State)

Closed\_list.push(Start State)

while(open\_list is not empty)

1.  $s \leftarrow$  remove min. f-value state from open\_list  
(if tie in f-values, select one w/ larger g-value)

3a. if  $s$  = goal node then trace path back to start; STOP!

3b. Generate successors/neighbors of  $s$ , compute their f values, and add them to open\_list and closed\_list if they are not in the closed\_list

...

The first occurrence of a board has to be on the shortest path to the solution

# BETWEENNESS CENTRALITY

# BC Algorithm Overview

- What's the most central vertex(es) in the graph below?
- How do we define "centrality"?
- Betweenness centrality defines "centrality" as the nodes that are between the most other pairs

Sample Graph

Graph 1

Graph 2

# BC Algorithm Overview

- Betweenness centrality (BC) defines "centrality" as the nodes that are between (i.e. on the path between) the most other pairs of vertices
- BC considers betweenness on only "**shortest**" paths!
- To compute centrality score for each vertex we need to find shortest paths between all pairs...
  - Use the Breadth-First Search (BFS) algorithm to do this

Sample Graph

Original 1

Original w/  
added path

Are these gray nodes  
'between' a and e?

No, a-c-d-e is the  
shortest path?

# BC Algorithm Overview

- Betweenness-Centrality determines "centrality" as the number of shortest paths from all-pairs upon which a vertex lies
- Consider the sample graph below
  - Each external vertex (a, b, e, f) lies is a member of only the shortest paths between itself and each other vertex
  - Vertices c and d lie on greater number of shortest paths and thus will be scored higher

Sample Graph

**Imagine each vertex is a ball and each edge is a chain or string. What would this graph look like if you picked it up by vertex c? Vertex a?**

# BC Implementation

- Based on Brandes' formulation for unweighted graphs
  - Perform  $|V|$  Breadth-first traversals
  - Traversals result in a subgraph consisting of shortest paths from root to all other vertices
  - Messages are then sent back up the subgraph from "leaf" vertices to the root summing the percentage of shortest-paths each vertex is a member of
  - Summing a vertex's score from each traversal yields overall BC result

Sample Graph with final BC scores

Traversals from selected roots and resulting partial BC scores (in this case, the number of descendants)

# BC Implementation

- As you work down, track # of shortest paths running through a vertex and its predecessor(s)
- On your way up, sum the nodes beneath

# of shortest paths thru the vertex,  
[List of predecessor]

Score on the way back up (if  
multiple shortest paths, split the  
score appropriately)

Traversals from  
selected roots  
and resulting  
partial BC scores  
(in this case, the  
number of  
descendants)
